Abstract

We compare and contrast time-series momentum (TSMOM) and moving average (MA) trading rules so as to better understand the sources of their profitability. These rules are closely related; however there are important differences. TSMOM signals occur at points that coincide with a MA direction change, whereas MA buy (sell) signals only require price to move above (below) a MA. Our empirical results show MA rules frequently give earlier signals leading to meaningful return gains. Both rules perform best outside of large stock series which may explain the puzzle of their popularity with investors yet lack of supportive evidence in academic studies.

1. Introduction

In a recent paper, Moskowitz, Ooi, and Pedersen (2012) introduce a "time-series momentum" (TSMOM) trading rule.[1] They find these rules, which generate a buy signal when the price is higher than a historical, say 200 days prior, price have strong predictive power.[2] We compare and contrast TSMOM rules and moving average (MA) rules that involve buying an asset when its price moves above its average price over a prior period. By comparing these rules we are able to provide insight into the sources of the returns they generate. While similar, these rules do not always generate buy and sell signals at the same time. Figures 1a and b give an example of a faster MA buy signal using S&P 500 data. Price moves above the 200-day moving average (signalling a buy) much sooner than the point where the 200-day return turns positive (necessary for a time-series momentum buy signal). We investigate TSMOM and MA rules in the US and internationally, in different economic and market states, and consider their susceptibility to crash risk.

[Insert Figures 1a and 1b about Here]

There is a puzzling disconnect between the popularity of past price based trading rules with the investment community (e.g. Hutchinson and O'Brien, 2014) and academic papers such as Olson (1999) which find these rules have not added value in the last few decades. We

[1] This is different to the Jegadeesh and Titman (1993) momentum anomaly which focuses on cross-sectional return comparisons. Here an asset would be purchased if it was among those with the strongest past returns, even if the asset's price had declined during the evaluation period and the relative out-performance was simply due to its returns being less negative than its peers. In contrast, a time-series momentum strategy would not buy this asset until it had positive past returns.

[2] Other papers also find support for time-series momentum. Baltas and Kosowski (2013) show volatility estimators can be used to improve the performance of time-series momentum strategies and Antonacci (2013) shows time-series momentum or "absolute momentum" as they call it has value as a stand-alone or overlay strategy.

investigate whether this may be due to trading rules being less effective on large stock dominated market indices that many tests have been conducted on.

Brown and Jennings (1989) were among the first to provide theoretical support for technical analysis. They show that investors can use past prices to gain insight into private information in situations where there is incomplete information. More recently, Zhu and Zhou (2009) show that moving average trading rules can improve asset allocation decisions by capturing return predictability. The theoretical work that underpins cross-section momentum also helps explain TSMOM. Hong and Stein (1999) suggest prices can move in trends when information diffuses slowly into prices as a result of "news watchers" in the market. Barberis, Shleifer, and Vishny (1998) show the behavoral biases of conservatism and anchoring lead to underreaction, while Daniel, Hirshleifer, and Subrahmanyam (1998) suggest investors can be overconfident about the accuracy of their private information and this leads to momentum.

TSMOM and MA rules are clearly closely related. TSMOM rules signal a buy (sell) when price moves above (below) a historical price at a certain historical point, while MA rules signal a buy (sell) when price moves above (below) the average price over a historical period. However, there are important differences in the timing of the signals generated by TSMOM and MA rules. We formalize the relation between TSMOM and MA rules and show that TSMOM entry and exit signals are generated when a MA changes direction. Given that a MA is the average of multiple prices, a price change is more likely to result in price moving above (below) the MA, as required for a MA entry (exit) signal, than a MA direction change as required for a TSMOM signal. As such, the signals generated by MA rules are likely to occur before TSMOM signals.

Our empirical results are consistent with these notions. The correlation of the returns generated by long-only TSMOM and MA rules are 0.78 or higher. However, while there is a strong relation between the returns from TSMOM and MA rules, there is a consistent pattern of MA rules generating larger returns, and larger Sharpe Ratios and Fama and French (1993) / Carhart (1997) four-factor alphas.[3] Our core results are from "long-only" rules which lead to stock market investment following buy-signals and T-bill investment following sell-signals. However, we verify our results also hold for rules that take short market positions.

We decompose the periods where MA and TSMOM rules are not in the market together and find periods where either MA or TSMOM strategies enter the market before the other rule are characterised by relatively large positive daily returns on average. MA rules generates earlier buy signals more frequently which contributes to its return advantage over TSMOM rules. Moreover, TSMOM strategies are more likely to result in a position remaining open longer than MA strategies. When this occurs daily returns are negative on average. The earlier closing of MA positions in these instances is of further benefit to MA rules.

The majority of MA rules generate breakeven transaction cost levels that appear to be larger than the actual transaction costs an investor would face. These one-way breakeven costs range from 42 to 69 basis points for rules with 10 to 150 look-back periods. These are larger than the 40 basis points transaction cost which we estimate for our sample period, based on the Jones (2002) estimate of one-way transaction costs (half spread + NYSE commission) of around 100 basis points in 1970 and 20 basis points in 2000. This indicates the rules generate profits after transaction costs. The higher breakeven costs for TSMOM rules reflects that fact that these typically lead to positions being held for longer than their MA equivalents and this lower

[3] These results are not inconsistent. The average monthly return on cross-sectional momentum winner stocks (from Ken French's website) over the 1963 – 2011 period is 1.51% compared to 0.88% for the CRSP value-weighted index. However, the correlation between these two series is 0.85.

portfolio turnover results in larger breakeven transaction costs even though the gross of transaction cost TSMOM returns are lower than their MA equivalents.

We compare and contrast the performance of TSMOM and MA rules on CRSP size quintile indices.[4] Previous empirical tests of MA and TSMOM on equity markets have mostly focused on market indices.[5] However, there is good reason to believe these techniques, which capture price continuation, may be more successful on stocks other than the large stocks which dominate market indices. Bhushan (1989) shows analysts focus on large stocks, while Hong, Lim, and Stein (2000, p. 267) suggest "stocks with lower analyst coverage should, all else equal, be ones where firm-specific information moves more slowly across the investing public." More recently, Han, Yan, and Zhou (2012) find that size and volatility indices are closely related and that MA rules are particularly profitable in volatile assets. This is consistent with Zhang (2006) who finds that greater information uncertainty, which can be measured by the standard deviation of returns, leads to greater short-term price continuation. Our results indicate both MA and TSMOM rules perform much better on stocks other than those in the largest quintile. Their good performance is not limited to the smallest stocks but rather is absent in the largest stocks. This finding could help explain why technical analysis remains popular with investors despite academic studies, which tend to focus on market index data, typically finding these rules add no value.[6]

The issue of data snooping is ever present when investigating return predictability. It is always possible that a trading rule appears to be profitable by chance when it is applied to a

---

[4] We thank Ken French for making these data available on his website.

[5] MA examples include Brock, Lakonishok, and LeBaron (1992) for the US and Ratner and Leal (1999) for Asian and Latin American markets. The TSMOM paper of Moskowitz, Ooi, and Pedersen (2012) is also based on equity indices / futures contracts on these indices. A MA exception is Lo, Mamaysky, and Wang (2000) who consider US stocks from different size quintiles.

[6] The results of Neely, Rapach, Tu, and Zhou (2010) suggest another explanation. They find technical trading rules complement predictions based on fundamental factors.

particular data series. Lakonishok and Smidt (1988, p. 404) suggest a good way to avoid this is to test anomalies “in data samples that are different from those in which they were originally discovered.” The important technical analysis paper of Brock, Lakonishok, and LeBaron (1992) finds moving average rules like the ones we test add value when they are applied to the Dow Jones Industrial Average (DJIA) over the 1897 – 1986 period. We therefore consider the 1987 – 2013 sub-period to ensure we have an out-of-sample test. The MA alphas for series other than the large stock series remain statistically significant in this period, while the TSMOM alphas are statistically significant on the smallest and middle stock portfolios. MA alphas are larger than their TSMOM equivalents in both sub-periods, however the differences are more marked in the earlier period. Our results are also robust in the ten international markets studied by Rapach, Strauss, and Zhou (2013). While MA and TSMOM strategies both generate statistically significant alphas, there is a consistent pattern of larger alphas to MA rules.

Daniel and Moskowitz (2011) and Barroso and Santa-Clara (2014) show cross-sectional momentum is susceptible to periods of persistent negative returns. This “crash risk” arises following periods of large market declines when the past loser portfolio (where a momentum investor is short) strongly out-performs the past winner long portfolio. These momentum crash risk papers are related to the work of Cooper, Gutierrez, and Hameed (2004) who show momentum returns are positive (negative) when the past three-year market return is positive (negative). We show that neither TSMOM nor MA rules are very susceptible to crash risk. The worst monthly returns from these rules are rarely much worse than those to a buy-and-hold strategy. The worst MA rule returns are frequently better than their TSMOM equivalents so there is no evidence that the larger MA alphas are compensation for crash risk.

The rest of this paper is structured as follows: Section 2 contains a description of the MA and TSMOM trading rules and data. The key tests are described and the results are presented and discussed in Section 3. Additional results are presented and discussed in Section 4, while Section 5 concludes the paper.

2. Trading Rules and Data

The MA rules and TSMOM rules we study are both easy to implement. The MA rules are the popular "moving average" rules. Our base tests are conducted on what Brock, Lakonishok, and LeBaron (1992) refer to as "variable-length moving average rules", which is calculated as follows:

$$MA_{t,n} = \frac{P_{t-n+1} + P_{t-n+2} + \cdots + P_t}{n} \tag{1}$$

A buy signal is generated on day *t* when:

$$MAR_{t,n} = P_t - MA_{t,n} > 0 \quad \text{or} \tag{2a}$$

$$MAR_{t,n} = P_t - \frac{P_{t-n+1} + P_{t-n+2} + \cdots + P_t}{n} > 0 \tag{2b}$$

where *n* is the length of the moving average or "look-back period". This long equity market position is maintained until price moves below the moving average. The returns following a buy signal are therefore R_{t+1}, $R_{t+2}, \ldots,$ R_{t+k+1}. In our core test, we follow Han, Yan, and Zhou (2011) and invest in the risk-free asset at times when there is no buy signal. An alternative approach, which is also applied in the literature, is to take a short position during these times. This assumes that short sale positions can always be entered, which may not be accurate, so we limit our analysis of this approach to a robustness check. We also generate results for what Brock, Lakonishok, and LeBaron (1992) calls a "fixed-length moving average" rule. Here a position is held for a pre-determined number of days regardless of whether price has remained above the moving average of past prices or not.

The TSMOM rule we implement generates a buy signal on day *t* when:

$$TSMOM_{t,n} = P_t - P_{t-n} > 0 \tag{3}$$

A sell signals occurs when the price moves below the historical price. This results in the returns R_{t+1}, $R_{t+2}, \ldots,$ R_{t+k+1}. While Moskowitz, Ooi, and Pedersen (2012) test the statistical significance of trend following strategies using a time series regression model involving the returns in a current period regressed on the returns in a previous period, they implement the trading rule by going long (short) if the returns in the previous period are positive (negative).

Our base test involves an investment in the risk-free asset when there is no buy signal. However we also test a rule that enters short positions during these periods. This approach is particularly appropriate in markets where short positions are readily established, such as the futures markets studied by Moskowitz, Ooi, and Pedersen (2012). We also test a TSMOM rule that leads to investors remaining in the market for a fixed period regardless of where the current price is in relation to the historical price.

We follow Han, Yan, and Zhou (2012) and Moskowitz, Ooi, and Pedersen (2012) and test rules with a variety of look-back periods. The longest look-back period is 200 days which is consistent with the longest interval in Han, Yan, and Zhou (2012) and similar to the 12-month look-back period that Moskowitz, Ooi, and Pedersen (2012) focus on for the majority of their analysis. We also test periods of 10, 50, and 100 days. A 10-day look-back period is the focus of Han, Yan, and Zhou (2012). Brock, Lakonishok, and LeBaron (1992) consider periods from 50 to 200 days in their seminal paper.

Equations 4a, 4b, and 5 prove it can be shown mathematically that TSMOM rule buy signals are related to changes in MA direction.[7]

$$MA_{t,n} - MA_{t-1,n} = \frac{P_t - P_{t-n}}{n} \tag{4a}$$

or

$$MA_{t,n} - MA_{t-1,n} = \frac{TSMOM_{t,n}}{n} \tag{4b}$$

so

$$TSMOM_{t,n} = n \times (MA_{t,n} - MA_{t-1,n}) \tag{5}$$

Given equations 3 and 5, we can see a buy signal occurs when there is a movement from:

$$n \times (MA_{t,n} - MA_{t-1,n}) < 0 \tag{6a}$$

to

$$n \times (MA_{t,n} - MA_{t-1,n}) > 0 \tag{6b}$$

As equations 6a-6b show, a TSMOM buy signal does not occur until the MA changes direction (passes an inflection point). Since a MA buy signal only requires price to move above

[7] We are grateful to Henry C. Stern for explaining the equations and discussion in this section to us.

the moving average, whereas a TSMOM buy signal requires the MA itself to change direction, MA buy and sell signals are likely to occur before TSMOM buy and sell signals. Moving averages are most likely to change direction following a more sustained change in price over consecutive days.

We use value-weighted size quintile portfolios from Ken French's website for the 1963 – 2013 period for our base tests. As part of our analysis we want to document the similarity and differences between the returns to TSMOM and MA rules across the portfolios of different size after well-known factors like size, value, cross-sectional momentum, and the market factor are accounted for, so we obtain these data from Ken French's website. We also run tests on the ten international markets studied by Rapach, Strauss, and Zhou (2013). These include Australia, Canada, France, Germany, Italy, Japan, the Netherlands, Sweden, Switzerland, and the United Kingdom. The international sample period is 1973 – 2013. The equity index data are Thomson Reuters Datastream indices in local currency, while the T-bill data are from Global Financial Data. As a final step, we consider a World ex US index which is the total world market excluding the US from Thomson Reuters Datastream. The risk free proxy for this analysis is the equal weight of the risk free rate from the ten countries we mention above.

3. Main Results

3.1. Correlations and Raw and Risk-Adjusted Returns Comparison

In Table 1 Panel A, we report the monthly return correlations of the long-only MA and TSMOM strategies for the four look-back periods we consider (10 days, 50 days, 100 days, and 200 days). The correlations tend to be larger in the small stock portfolio and for the 10-day look-back period. However, the correlations are all high (0.78 and above). It is evident that MA and TSMOM rules are closely related.

The mean monthly returns in Panel B clearly demonstrate that both MA and TSMOM rules generate the largest returns on the smallest quintile one portfolio and the smallest returns on the largest quintile five portfolio. The average return across the eight MA and TSMOM rules is 1.64% for the quintile one portfolio compared to 0.80% for the quintile five portfolio. The rules based around shorter look-back periods also produce larger returns than their longer look-back period equivalents. The mean monthly return across the five quintile portfolios for MA and TSMOM is 1.56% for the 10-day look-back period compared to 1.06% for the 200-day look-back period. The mean returns generated by all the MA and TSMOM rules are statistically significantly different to zero. It is also clearly evident that MA rules consistently generate larger returns than their TSMOM equivalents and that these differences are typically statistically significant. We use *, **, and *** to indicate MA and TSMOM means that are statistically significantly different to each other at the 10%, 5%, and 1% level respectively. The out-performance of MA rules is stronger in smaller stock series and for shorter look back periods. This out-performance averages 0.33% in the quintile one portfolio and 0.14% in the quintile five portfolio.

MA rules consistently generate larger Sharpe ratios than their TSMOM equivalents and both methods give larger Sharpe ratios when they are applied to smaller stock series and when shorter look-back periods are used. For instance, the Sharpe ratio of MA (TSMOM) rules for a 10-day look-back period on the quintile one portfolio is 0.46 (0.40) compared to Sharpe ratios for MA (TSMOM) rules of 0.15 (0.12) for a 200-day look-back period on the quintile five portfolio.

Panel D contains the alphas from the Fama and French (1993) / Carhart (1997) four-factor model. As such, these alphas are net of market, size, value, and cross-sectional momentum effects. These monthly alphas show a similar trend to the Sharpe ratios. MA alphas are consistently larger than their TSMOM equivalents. We highlight in bold alphas that are statistically significant to zero at the 10% level or more, while *, **, and *** indicate MA and TSMOM alphas that are statistically significantly different to each other at the 10%, 5%, and 1% level respectively (based on the Wald test in a system of equations approach). Both rules generate larger alphas on the smaller stock portfolios with shorter look-back periods. The monthly MA (TSMOM) alphas for the 10-day look-back period on the quintile one portfolio are 1.52% (1.25%) and these decline to 0.12% (-0.01%) for 200-day look-back periods and the quintile five portfolio. In Section 4 we present results which indicate that the conclusions from the Table 2 results are robust in different sub-periods, across the business cycle, in international markets, when short-positions are entered following sell signals, and when positions are held for fixed holding periods.

[Insert Table 1 About Here]

3.3. Return Difference Decompositions

It is clear from the holding period correlations in Table 1 that long market or T-bill positions signalled by MA and TSMOM strategies are consistent for the majority of the time. The return differences we document in Table 1 come from periods when one rule has signalled a long market position and the other has not, so we examine these instances in detail in Table 2.

Both the MA and TSMOM strategies involve a look-back period of 50 days.[8] The first scenario "Same" includes days when both MA and TSMOM strategies are long the equity market or invested in the T-bill at the same time. This is the most common situation. For example, in the small stock portfolio Same occurs in 11,114 out of a total of 12,334 sample days, which represents 90% of the time. Once these situations occur, they last for a relatively long time (11 days) and the average return on these days is 0.06%. The days when MA and TSMOM rules generate different signals can be classified into six mutually exclusive scenarios. Scenarios "MA Early" and "TSMOM Early" are periods when MA (TSMOM) rules signal long positions first and TSMOM (MA) long position signals follow. Scenarios "MA Late" ("TSMOM Late") are periods when just the MA (TSMOM) rule remains in the market following a period when both MA and TSMOM have signalled long positions. Scenario "MA Only" ("TSMOM Only") are periods when MA (TSMOM) strategies have signalled long market positions and the other rule has not.

In the small stock portfolio, the average returns on MA Early and TSMOM Early days are 0.42% and 0.61% respectively, which are much larger than those in the Same Scenario. Establishing a long equity market position early that is subsequently followed by the other strategy leads to positive returns for both strategies. However, the MA rule is far more likely to be in this situation (34% of all days where the strategies signal different positions, compared to just 3% for TSMOM rules). MA Late (TSMOM Late) is when the MA (TSMOM) rule is in the market last following a period when both MA and TSMOM rules have signalled long positions. It is much more common for TSMOM strategies to stay in the market longer (41% of all days with deviations). Moreover, the market returns are -0.11% on these days on average. Staying in

[8] We present results for the 50-day look-back period as it is in between the shortest (10 days) and longest (200 days) look-back periods. Results for the other look-back periods are available on request.

the market longer tends to hurt TSMOM investors. MA rules are less likely to signal positions staying open longer than TSMOM rules (just 6% of deviation days) so the negative returns associated with these periods have less of an impact. Both MA Only and TSMOM Only occur relatively infrequently (11% and 5% of deviation days respectively). However, when they do occur, market returns are negative on average (-0.70% and -0.40% respectively).

It is important to note that the returns in Table 2 are not directly comparable to the mean returns in Table 1. The Table 1 returns include those earned from being invested in the T-bill and they are monthly returns which have been generated from compounding daily returns. However, the Table 2 returns can be used to get insight into the difference between the Table 1 mean MA and TSMOM rule returns. These differences are most pronounced for the small stock portfolio and the size of the difference decreases monotonically as the portfolio size increases. There is very little difference between the mean MA and TSMOM rule returns in the large stock portfolio. As such, we would expect the very apparent differences between MA and TSMOM returns in Panel A of Table 2 to reduce in Panels B – E. The results indicate this is the case. The main difference in Panel E over Panel A is that the mean TSMOM return in TSMOM Early is higher. This higher return in periods when the TSMOM rule is first to enter a long position offsets some of the negative relative performance of the TSMOM strategy in the other scenarios. It is also clear that the losses from the unique MA signals are larger those to TSMOM signals. However, the net weighted average return, which is obtained by multiplying the unique MA strategy returns by the proportion of times they occur and deducting the product of the unique TSMOM strategy return and the proportion of times they occur, is still relatively large.

[Insert Table 2 About Here]

We also investigate whether a combined strategy that only enters and exits positions when both MA and TSMOM rules are in agreement performs better than individual MA and TSMOM strategies. The Appendix 1 results indicate this is not the case. The mean returns and Jensen alphas of the combined strategy are typically lower than those for the standalone MA strategy, as documented in Table 1.

3.4. Transaction Cost Analysis

We estimate the one-way breakeven transaction costs by comparing TA and TSMOM rule returns to the returns to a buy-and- hold strategy and present the results in Table 3. These are larger for smaller quintile portfolios and 50-day look-back periods. While the 10-day look-back rules generate the larger pre-transaction cost returns, the more frequent turnover that these rules require often results in lower breakeven transaction costs than rules with longer look-back periods and less frequent trading. Jones (2002) estimates one-way transaction costs (half spread + NYSE commission) of around 100 basis points in 1970 and 20 basis points in 2000 for NYSE stocks. Given transaction costs have likely declined further since 2000, it seems reasonable to assume average transaction costs of around 40 basis points over our sample period. The average breakeven transaction cost for 10-day, 50-day, and 150-day look-back periods for MA rules range from 42 to 69 basis points so these rules appear to generate positive returns after transaction costs. The breakeven transaction costs for TSMOM rules are never larger than 28 basis points so these rules do not appear to result in profits after transaction costs. Some rules have negative breakeven transactions which they do not generate returns over and above buy-and-hold returns even before transaction costs are accounted for. The results in panels C and D indicate TSMOM rules typically lead to positions being held for longer than their MA equivalents. However, in spite of this, TSMOM rules have smaller breakeven transaction costs on account of their lower pre-transaction cost returns.

[Insert Table 3 About Here]

3.5. Downside and Higher Moment Risk

Daniel and Moskowitz (2011) and Barroso and Santa-Clara (2014) both document that cross-sectional momentum is susceptible to "crash risk". These periods of persistent negative returns can be a substantial risk for cross-sectional momentum investors. In Table 4 we focus on the lowest monthly returns generated by TSMOM (MA) strategies and compare them to the returns experienced by a MA (TSMOM) investor in that same month. We also document the returns a buy-and-hold investor would have earned in each of these months. Finally, we present the returns to TSMOM and MA strategies in the months when the buy-and-hold returns are the lowest. We present results for a look-back period of 50 days for the small portfolio and the middle size portfolio. As documented previously, neither MA nor TSMOM strategies perform well on the large portfolio. The results also indicate that neither the TSMOM nor MA approaches are particularly susceptible to crash risk. It is clear that both MA and TSMOM rules typically move the investor to the T-bill investment prior to sustained market declines. Moreover, the downside returns of MA rules are less severe than their TSMOM rule equivalents. Crash risk compensation is not driving the higher MA rule returns.

The Panel A results indicate the lowest monthly return for the MA rule in the small stock portfolio is -8.77%, which occurred in March 2000. In this month the buy-and-hold return was -10.51%. The MA rule return is not as low because it was invested in T-bills for some of the days in the month where the buy-and-hold investor earned negative returns from the equity market. Of the ten negative MA strategy return months there are only two situations when the buy-and-hold return is positive. The four months with the most negative MA rule returns coincide with more negative TSMOM returns which is some indication that MA is less susceptible to crash risk.

The Panel B results relate to the lowest ten TSMOM monthly rule returns. The worst TSMOM return is a loss of 14.02%, which is clearly a larger loss than the worst MA monthly loss (-8.77%). Moreover, the TSMOM strategy returns are consistently lower than the MA strategy returns. This further emphasizes that MA rules are less susceptible to downside risk than TSMOM.

The Panel C results show that both TSMOM and MA approaches have considerably less downside risk than a buy-and-hold strategy. The lowest buy-and-hold return in the small portfolio was October 1987. In this month the loss was 29.62%. Investors adopting a TSMOM or MA trading rule would have lost less than 1% in this month. In the second worst buy-and-hold return month (August 1998) both TSMOM and MA generated small positive returns.

[Insert Table 4 About Here]

Barroso and Santa-Clara (2014) point out cross-sectional momentum strategies can experience large crashes. Although such strategies may be profitable on average they may not be appealing to an investor with a reasonable level of risk aversion. They suggest it is therefore important to consider the higher moments of any trading strategy. The Table 5 results show the MA and TSMOM strategies generate larger returns on the size quintile indices (other than the top two quintiles) than the returns from the size, value, or cross-sectional momentum factors. As Barroso and Santa-Clara (2014) document, cross-sectional momentum has large negative skewness, but this is not present in the MA or TSMOM rule results. Rather, the MA rule generates relatively large positive skewness. MA strategy returns have lower kurtosis than their TSMOM equivalents but both rules have kurtosis that is considerably lower than that in the cross-sectional momentum rules.

[Insert Table 5 About Here]

Daniel and Moskowitz (2011) also consider market timing and the sources of crash risk in cross-sectional momentum portfolios using a number of models. We apply the logic behind these models to investigate crash risk in both TSMOM and MA rules. The results are presented in Table 6.

$$r_{P,t} - r_{f,t} = [\alpha_0 + \alpha_B I_B] + [\beta_0 + \beta_B I_B + \beta_{B,U} I_B I_U](r_{m,t} - r_{f,t}) + \varepsilon_t \tag{7}$$

$$r_{P,t} - r_{f,t} = \gamma_0 + \gamma_B I_B + \gamma_{mkt}\sigma_m^2 + \gamma_{highstress} I_B \sigma_{m,t}^2 + \upsilon_t \tag{8}$$

Where[9]:

$r_{P,t}$ is the return on either the TSMOM or MA portfolio in month *t*.

[9] See Daniel and Moskowitz (2011) for more detail on these variables.

$r_{f,t}$ is the return on the Treasury bill in month *t*.

$r_{m,t}$ is the return on the CRSP VW portfolio in month *t*.

I_B is an ex-ante indicator variable for bear-markets. If the CRSP VW index return is negative (positive) in the prior 24 months prior to month *t*, the variable is 1 (0).

I_U is a contemporaneous up-month indicator variable. If the CRSP VW index return is positive (negative) in month *t*, the variable is 1 (0).

σ_m^2 is an ex-ante market volatility estimate for the next month. We use the standard deviation of the CRSP VW index return over the 50 days prior to month *t*.

[Insert Table 6 About Here]

The conditional CAPM in equation 7 examines the alpha and beta differences in bear markets versus other periods. For the TSMOM portfolio, the alpha difference between the bear periods and other periods, α_B, is not significantly different from zero in any of the size quintile portfolios. The change in alphas driven by the bear periods are also insignificant for the size quintile 1 portfolio for the MA rule. However, the impact of the bear period significantly reduces the alphas of the medium and large size MA strategy portfolios.

During the bear period, the betas have a statistically significantly decline across all size quintile portfolios for both TSMOM and MA rules, which indicates that the portfolio returns become less sensitive to the downside market movement. This implies the TSMOM and MA strategies tend to switch to the T-bill during bear periods. The coefficient $\beta_{B,U}$ captures the sensitivity of the strategy return to changes in market direction. The significantly positive $\beta_{B,U}$

suggests that the portfolio exposure increases with the contemporaneous positive market movement. This confirms the market timing ability of both TSMOM and MA strategies.

Equation 8 examines the impact of market stress on the TSMOM and MA strategies. When the market volatility is high in bear periods, the estimated coefficients $\gamma_{highstress}$ in all size quintile portfolios are not statistically different from zero, so both TSMOM and MA are immune to the high market stress periods in bear markets.

4. Additional Results

4.1. Sub-Period Results

We test the robustness of our claims, based on the full-sample Table 1 and 2 results, in different periods in Appendix 2. We consider two sub-periods. The most recent sub-period of 1987 – 2013 is chosen to ensure we have an "out-of-sample" period that follows the 1887 – 1986 period used by the important moving average technical analysis paper of Brock, Lakonishok, and LeBaron (1992). Lakonishok and Smidt (1988) note that an effective tool to combat data mining bias is to use datasets different from those researchers use to first document the same anomalies.[10]

The Panel A results show the correlations are large in both the early sub-period and the more recent one, but they are marginally larger in the earlier sub-period (average = 0.91) than the more recent period (average = 0.86). MA rules are profitable in both sub-periods. The alphas are consistently positive and statistically significantly different from zero in all but the large stock portfolio. The TSMOM alphas are statistically significant in the small and medium portfolios.

[10] The international market results we generate also address this issue.

The lack of robust predictability for MA in the recent period for the large stocks is consistent with Olson's (1999) finding that moving average trading rules are not profitable in the 1990s. MA alphas are larger than their TSMOM equivalents in both sub-periods. These differences are statistically significant for the first four portfolios in the 1965 – 1986 period and for the small portfolio in the 1987 – 2013 period.

Henkel, Martin, and Nardari (2011), Dangl and Halling (2012), and Rapach, Strauss, and Zhou (2013) all find that predictability is stronger in recessions than expansions. Cooper, Gutierrez and Hameed (2004) find the cross-sectional momentum strategy is only profitable if the market has been going up over the previous 36 months. The MA and TSMOM rule results for these states, which we report in Appendix 3, are consistent with the core results. The correlation between MA and TSMOM rule returns are high in all states and the MA alphas are consistently larger than their TSMOM equivalents.

4.2. International Results

We repeat our core analysis for the ten international markets considered by Rapach, Strauss, and Zhou. (2013). These are Australia, Canada, France, Germany, Italy, Japan, the Netherlands, Sweden, Switzerland, and the UK. We also include the MSCI World excluding US index. The results are for the long-only strategy and a look-back period of 50 days. The Table 7 Panel A results indicate the correlation between MA and TSMOM rule returns are large in each market. The correlations range from 0.81 in Australia to 0.91 in Sweden. Mean returns to MA rules are generally larger than those to TSMOM rules, which is also in accordance with the US results. MA and TSMOM rules perform the best in Sweden, Italy, and Australia and the worst in

Japan. The Sharpe ratio and Jensen alpha results are similar to the mean results in that they are higher for MA than TSMOM rules in the majority of countries.

[Insert Table 7 About Here]

Table 8 contains results which decompose return differences between MA and TSMOM rules for the MSCI World excluding US index. These results confirm those documented in Table 2 for the US. The “Same” scenario, where both the MA and TSMOM rules are in the equity market or T-bills on the same day occurs in 9,227 out of a total of 10,697 days, or 86% of the time. “MA Early” is over five times more common than “TSMOM Early”, so while the average return on days when the MA rule is long the equity market first are lower than those when TSMOM is in the market first, the fact that “MA Early” occurs more frequently results in a return advantage to the MA rule. Similar to the US results, “MA Late” is far less common than “TSMOM late” and the returns on days when the TSMOM rule is long the equity market and the MA has exited are negative, which contributes to the higher relative MA returns. The “MA Only” and “TSMOM Only” results are also similar to their US equivalents in that the average daily equity returns are negative when one rule signals a long equity market position and the other does not.

[Insert Table 8 About Here]

4.3. Short Position Results

If MA and TSMOM rules are as effective at signalling declines in the equity market as they are at signalling equity market increases then entering short equity market positions following market declines rather than investing in T-bills should generate larger returns than those in our base tests. In other words, the gains from short positions in the long / short approach will exceed the returns from being in T-bills in the long-only approach. The Appendix 4 results show that both MA and TSMOM rules do typically generate larger returns when short positions are permitted. In particular, the scenarios where the largest returns are generated, such as the 10-day look-back on the small portfolio, show a marked increase.

The MA (TSMOM) monthly Jensen's alpha increases from 1.52% (1.25%) in the long-only 10-day look-back scenario to 2.92% (2.33%) in the long / short approach. Lower returns are generated by long / short rules for some longer look-back rules on larger stock portfolios. However, what is clear is that the relation between MA and TSMOM strategy returns for any given size portfolio and look-back period are very similar regardless of whether the long-only or long / short settings are used. MA rules consistently have larger returns, larger Sharpe ratios, and larger Jensen alphas than their TSMOM equivalents. The statistical significance of the Jensen alpha differences also shows the same pattern of being stronger for rules with shorter look-back periods on smaller portfolios. Although the results in Appendix 4 are more appealing than those in Table 1, short-selling constraints often limit the ability of investors to take short positions in reality (e.g., Barberis and Thaler (2002)).

4.4. Fixed Holding Period Results

Another approach to implementing MA and TSMOM rules is to hold positions for a fixed period, ignoring any sell signals that occur before the end of this period. This period is the minimum holding period as a buy signal at the end of this period would result in the position being maintained. i.e., in reality, an individual would not sell a position one day and open a new position on that day. Rather, they would just keep their position open. Brock, Lakonishok, and LeBaron (1992) also test such a strategy, which they refer to as a "fixed-length moving average" approach, alongside the more flexible holding period approach we use for our base tests and did not find material differences between the two. We present results for a 50-day look-back period and a ten-day holding period in Appendix 5. These results are very similar to those in Table 1 in that the MA strategy consistently has higher returns, Sharpe ratios, and Jensen alphas than TSMOM.

5. Conclusions

Moving average trading rules and time-series momentum have developed as two separate parts of the return predictability literature. Moving averages rules generate a buy signal when the price moves above the average historical price over a defined number of days. Time-series momentum rules generate buy signals when the return over a past period is positive. This is distinct from cross-sectional momentum which generates buy signals based on the return of a security relative to the return of other securities.

We show moving average technical trading rules and time-series momentum rules are closely related. The returns generated by each method frequently have correlations that are in excess of 0.8. There are, however, important differences between the two. We document the relation between TSMOM and MA rules. TSMOM rule entry and exit signals are generated when a MA changes direction, which suggests that TSMOM rules tend to take longer than MA rules to give a buy or sell signal. After all, a price change is more likely to result in price moving above (below) the MA, which is required for a MA entry (exit) signal, than it is to cause a MA direction change, as required for a TSMOM signal.

Our empirical results are consistent with this finding. MA rules are more likely to signal a buy signal sooner and exit long positions more quickly, which lead to larger returns on average. MA rules also tend to generate larger Sharpe ratios and larger Jensen alphas than their TSMOM equivalents. We find that both trading rules are most profitable on stocks other than largest quintile stocks. Previous studies have shown moving average rules are not profitable on equities since the mid-1980s. We show this result holds for the largest stocks but not for mid-capitalization or small stocks. This may reconcile the puzzle of the continuing popularity of these rules with the investment community despite the lack of supportive evidence for these rules in studies using market indices dominated by large stocks.

Unlike cross-sectional momentum, neither MA nor TSMOM strategies are particularly susceptible to crash risk. Both these rules exit long positions prior to sustained market downturns. MA rules are better at this than their TSMOM equivalents so there is no evidence that larger returns accruing to MA rules are compensation for higher crash risk.

Data are CRSP quintile value-weighted size portfolios for the 1963 – 2013 period. Panel A contains monthly correlations of the returns produced by the long-only TSMOM and MA strategies for the four look-back periods (ranging from 10 days to 200 days). The mean and Sharpe ratios of monthly returns are in Panels B and C respectively. Panel D contains monthly alphas based on the four-factor model. Statistical significant means, Sharpe ratios, and alphas at the 10% level or more are in bold. *, **, and *** denote MA and TSMOM denote means, Sharpe Ratios, and alphas that statistically significantly different to the equivalent MA or TSMOM metric at the 10%, 5%, and 1% level respectively.

Average Return	0.04%	0.51%	0.93%	0.08%	-0.06%	-0.79%	-0.40%

Data are CRSP quintile value-weighted size portfolios for the 1963 – 2013 period. The MA and TSMOM strategies involve a look-back period of 50 days and investing in the equity market (T-bill) following a buy (sell) signal. Scenario “Same” is when both MA and TSMOM rules are long the equity market or T-bill at the same time. Scenario “MA Early” (“TSMOM Early”) is periods when MA (TSMOM) rules signal long positions first and TSMOM (MA) rule long position signals follow. Scenario “MA Late” (“TSMOM Late”) is when MA (TSMOM) rules are in the market last following a period when both MA and TSMOM rules have signalled long positions. Scenario “MA Only” (“TSMOM Only”) is periods when MA (TSMOM) rules have signalled long market positions and TSMOM (MA) rules have not. “Number of Instances” and “Number of Days” are the number of occasions that each scenario occurs and the total number of days of each scenario. The “Proportion of Daily Returns” is percentage of total days across scenarios 1-6 that each scenario represents. The “Average Return” is the average daily return (as a percentage) across the days in each scenario.

Table 3
Breakeven Transaction Costs

	Q1	Q2	Q3	Q4	Q5
	Panel A: Breakeven Transaction Costs - MA				
10	80	50	46	35	1
50	170	92	55	36	-8
100	147	46	26	17	-10
200	92	-5	-17	11	15
	Panel B: Breakeven Transaction Costs - TSMOM				
10	80	36	25	14	-16
50	91	10	16	5	-20
100	37	-29	-1	8	-1
200	-72	-118	-66	-56	-4

Data are CRSP quintile value-weighted size portfolios for the 1963 – 2013 period. The MA and TSMOM strategies involve a look-back period of 50 days and investing in the equity market (T-bill) following a buy (sell) signal. Panel A contains the lowest ten monthly returns for the TSMOM strategy and the corresponding MA strategy and buy-and-hold returns. Panel B contains the lowest monthly returns for the MA strategy and the corresponding TSMOM rule and buy-and-hold returns. The lowest ten monthly buy-and-hold returns and corresponding TSMOM and MA rule returns are in Panel C. Each part of the analysis is conducted separately for the small and middle stock portfolios.

Data are CRSP quintile value-weighted size portfolios for the 1963 – 2013 period. The MA and TSMOM strategies involve a look-back period of 50 days and investing in the equity market (T-bill) following a buy (sell) signal. The equation specifications are as per Daniel and Moskowitz (2011). Statistical significance at the 10%, 5%, and 1% level (based on Newey and West (1987) standard errors) are denoted by *, **, and *** respectively.

International results are calculated for the countries studied by Rapach, Strauss, and Zhou. (2013). Equity data are obtained from Thomson Reuters Datastream. T-Bill Data are from Global Financial Data. The data covers the 1973 – 2013 period. Returns are in local currency. The results are for the long-only strategy and a look-back period of 50 days. Statistical significant means, Sharpe ratios, and alphas at the 10% level or more are in bold. *, **, and *** denote MA and TSMOM denote means, Sharpe Ratios, and alphas that statistically significantly different to the equivalent MA or TSMOM metric at the 10%, 5%, and 1% level respectively.

Table 8
International Time-Series Momentum and Technical Analysis Difference Decomposition

Scenario	Same	MA Early	TSMOM Early	MA Late	TSMOM Late	MA Only	TSMOM Only
Number of Instances	421	59	27	64	155	66	44
Number of Days	9,227	324	57	163	574	233	119
Proportion of Daily Deviations		22%	4%	11%	39%	16%	8%
Average Return	0.04%	0.31%	0.62%	-0.04%	-0.07%	-0.35%	-0.22%

This is as per Table 2. MSCI World (Excluding U.S.) equity data are obtained from Thomson Reuters Datastream. T-Bill Data are from Global Financial Data. The data covers the 1973 – 2013 period.

Q5 (Large)	**0.35#**	0.07#	0.06	0.01	0.04	0.63

Data are CRSP quintile value-weighted size portfolios for the 1963 – 2013 period from Ken French's website. The MA and TSMOM strategies involve a look-back period of 50 days and investing in the equity market (T-bill) following a buy (sell) signal. Panel A contains return correlations by sub-period. Monthly alphas, based on the four-factor model, are in Panel B. Statistical significant alphas at the 10% level or more are in bold. p-values from a test of the statistical significance of the differences in MA and TSMOM alphas are also provided. We also run a t-test to determine whether the difference in MA (TSMOM) alphas between the two sub-periods are statistically significant. Those that are (at the 10% level or stronger) are denoted by a #.

Appendix 3
Performance and Comparison by Economic and Market State

Panel A: Correlations

The results are as per Table 1, except that short equity market positions are entered following sell signals. Statistical significant (based on Newey and West (1987) standard errors) alphas at the 10% level or more are in bold. *, **, and *** denote MA and TSMOM denote alphas that statistically significantly different at the 10%, 5%, and 1% level respectively.

Appendix 5
50-Day Look-Back Period and Ten-Day Minimum Holding Periods

	Q1 (Small)		Q2		Q3		Q4		Q5 (Large)	
	MA	TSMOM	MA	TSMOM	MA	TSMOM	MA	TSMOM	MA	TSMOM
Correlations	0.75		0.71		0.68		0.67		0.65	
Mean Returns	2.08	1.23	1.63	0.85	1.09	0.88	0.89	0.70	0.45	0.42
Sharpe Ratio	0.31	0.14	0.23	0.08	0.13	0.09	0.10	0.06	0.01	0.00
Jensen's Alpha	1.46***	0.43	1.09***	0.10	0.54**	0.18	0.31	-0.01	-0.11	-0.25

The results are as per Table 1, except that long equity market positions are held for a minimum of ten days regardless of whether there is a sell signal during this time or not. If there is still a buy signal after the ten day period the position is maintained. Statistical significant (based on Newey and West (1987) standard errors) alphas at the 10% level or more are in bold. *, **, and *** denote MA and TSMOM denote alphas that statistically significantly different at the 10%, 5%, and 1% level respectively.
