Outline

- Models in an exotic derivatives business
- Teaching a machine to think like a trader
- First steps: toy model trading
- Moving further into the real world

How are models used in an exotic derivatives business?

Pricing new trades

- Classical risk-neutral models are ubiquitous

$$\text{Price} \longrightarrow V_0 = E^Q \left[\frac{V_T}{B_T} \right] \longleftarrow \text{Expectation under risk-neutral measure}$$

- Disregard any existing portfolio and price the derivative under the assumption that perfect replication is possible
- Apply **local** adjustments: hedging costs (trader's estimate), model limitation adjustments, ...
- For larger trades, consider **global** adjustments depending on existing portfolio: credit charge, concentration charge, etc.

How are models used in an exotic derivatives business?

Hedging

- Compute the price with the usual classical model

$$V_0 = E^Q \left[\frac{V_T}{B_T} \right]$$

- Then compute “greeks”

$$\frac{\partial V_0}{\partial X}$$

- For factors which are stochastic in the model, and parameters which aren't (e.g. interest rates in a local volatility model)
- Based on the greeks, decide which hedging instruments to buy/sell
 - The right hedge is *not* just the model risk
 - Traders adjust the actual traded risk with “experience/skill”
 - He/she needs to be aware of transaction costs, market dynamics (such as vol-spot correlation), concentration and liquidity risk...

How are models used in an exotic derivatives business?

Apply constraints

- Internal: control the risks we take, ensure efficient use of capital
- External: regulatory, legal

Examples:

- Direct risk and stress limits based on the model:

$$L < \frac{\partial V_0}{\partial X} < U$$

$$V_0(X) - V_0(X + \text{stress}) < M$$

- Limits on CVaR
 - Capital requirements – many determining factors
 - Short selling bans
- These constraints are not usually part of the valuation model

Beyond the classical approach

- It should include transaction costs, lack of liquidity, and constraints
- This means accepting that perfect replication is impossible...

- We want to increase automation in the business
- The risk management model needs to do more

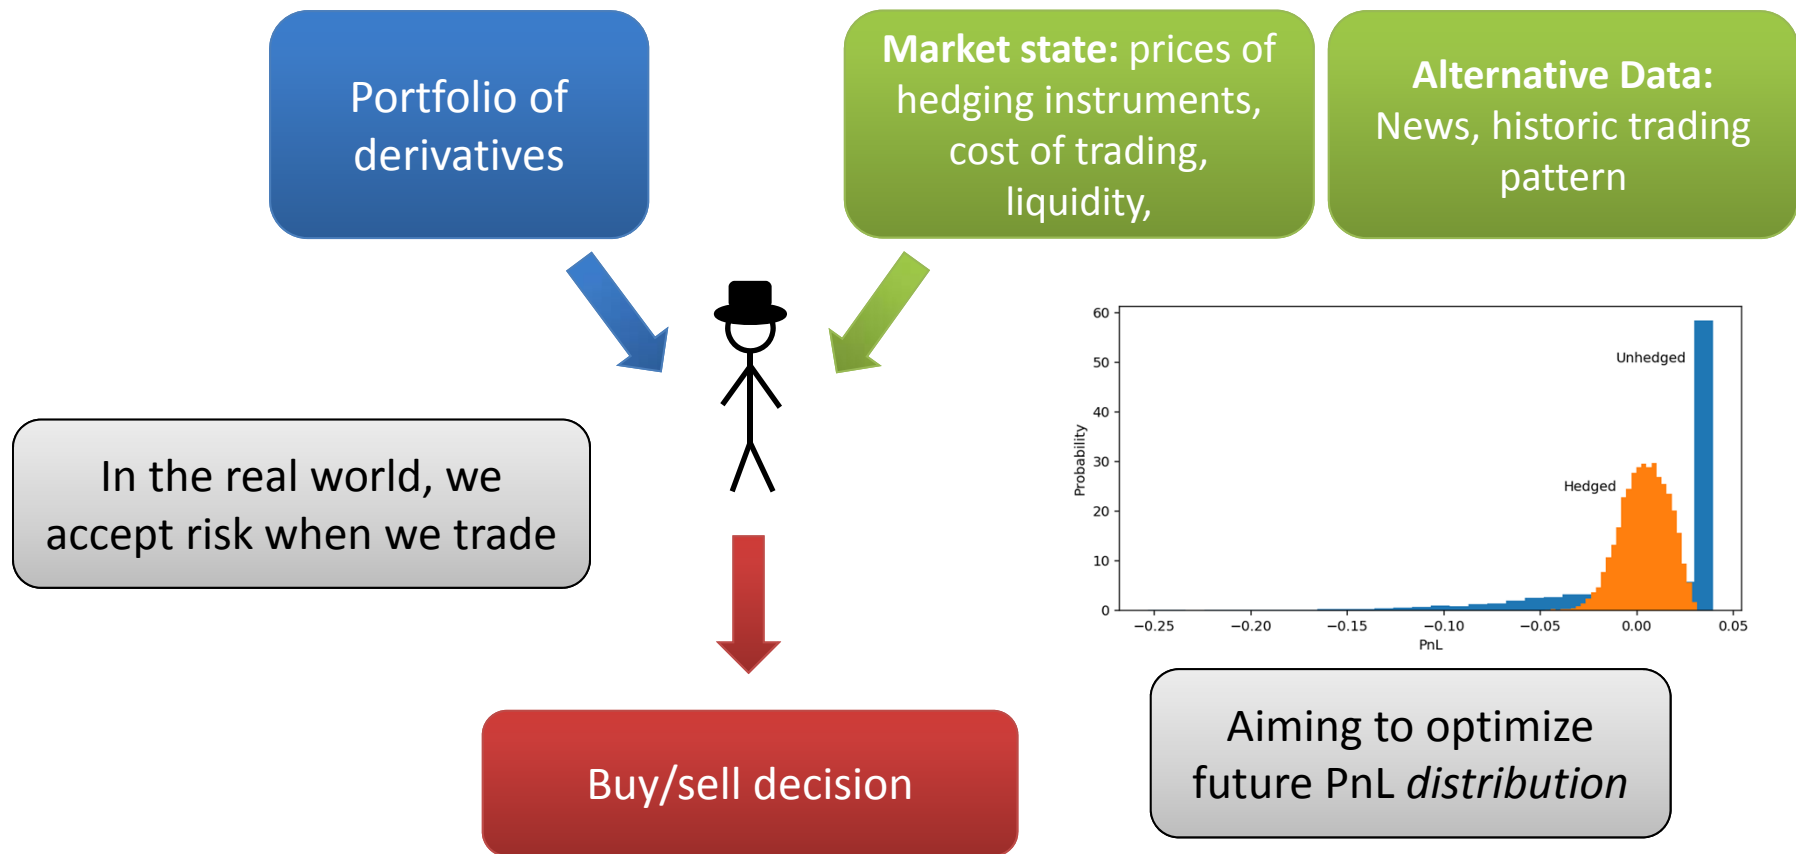

Outline

- Models in an exotic derivatives business
- Teaching a machine to think like a trader
- First steps: toy model trading
- Moving further into the real world

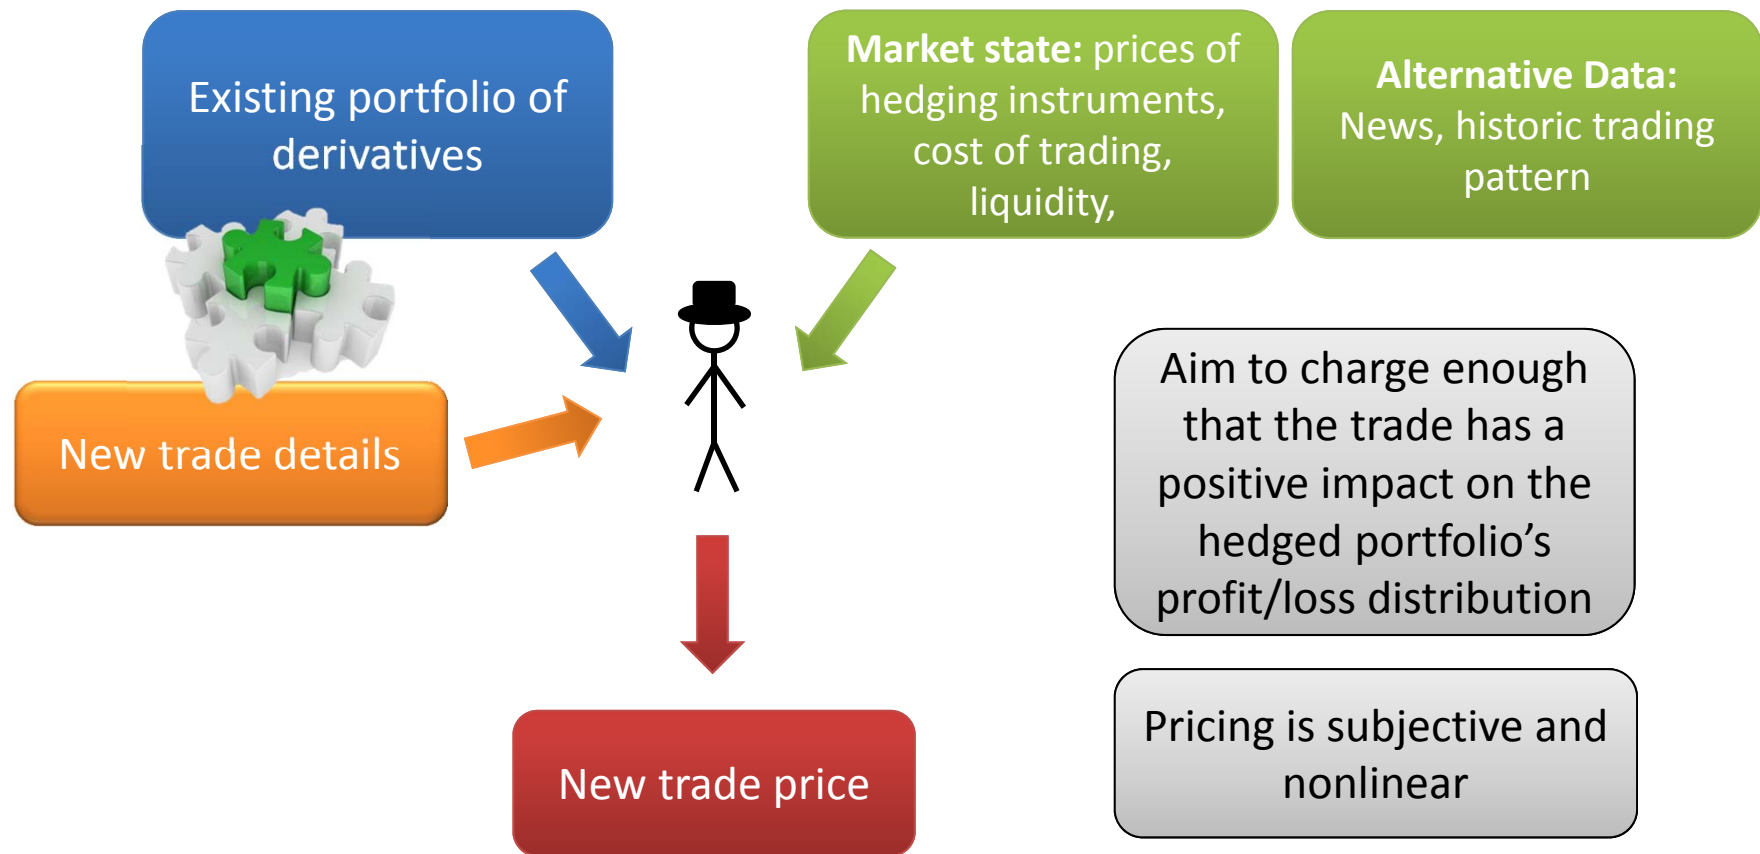

Trading inputs and outputs

- Risk management

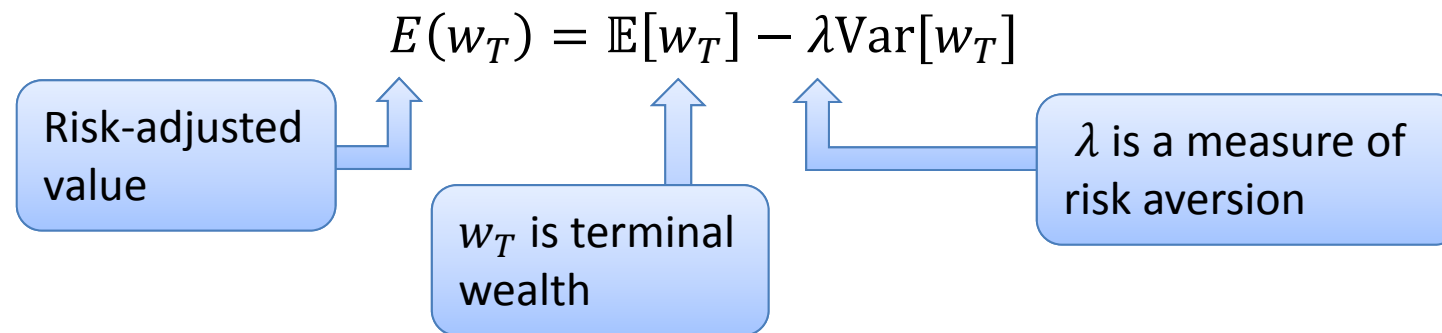

Trading inputs and outputs

- Pricing

How to compare profit/loss distributions?

- We could use classical “Markoviz” portfolio optimization
 - Maximize expected return while penalizing variance

- Note that $E(w_T)$ is a function on the *distribution* of terminal wealth
- But mean-variance is not a good measure if terminal wealth is not normally distributed
 - Exist on-monotone cases where $X \geq Y$ but $E(X) < E(Y)$

How to compare profit/loss distributions?

- What are sensible conditions for our risk-adjusted value function $E(w_T)$?

- Monotonicity

$$X \geq Y \Rightarrow E(X) \geq E(Y)$$

More is better

- Convexity

$$E(\alpha X + (1 - \alpha)Y) \geq \alpha E(X) + (1 - \alpha)E(Y), \alpha \in [0,1]$$

We are risk-averse

- Cash invariance

$$E(X + c) = E(X) + c$$

There is no risk adjustment for cash

$-E(\cdot)$ is a **convex risk**
measure

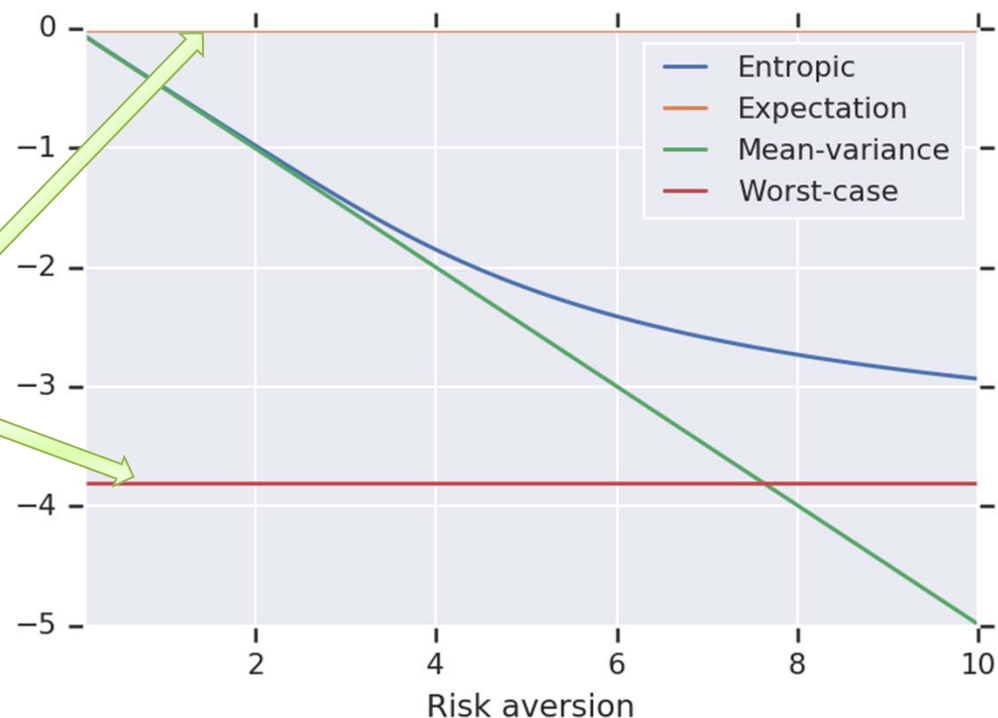

How to compare profit/loss distributions?

- We will mostly use the *entropic* measure: $E(X) = -\frac{1}{\lambda} \ln \mathbb{E}[e^{-\lambda X}]$
- Equivalent to mean-variance for small risk-aversion parameter λ :

$$-\frac{1}{\lambda} \ln \mathbb{E}[e^{-\lambda X}] = \mathbb{E}[X] - \frac{1}{2} \lambda \text{Var}[X] + \dots$$

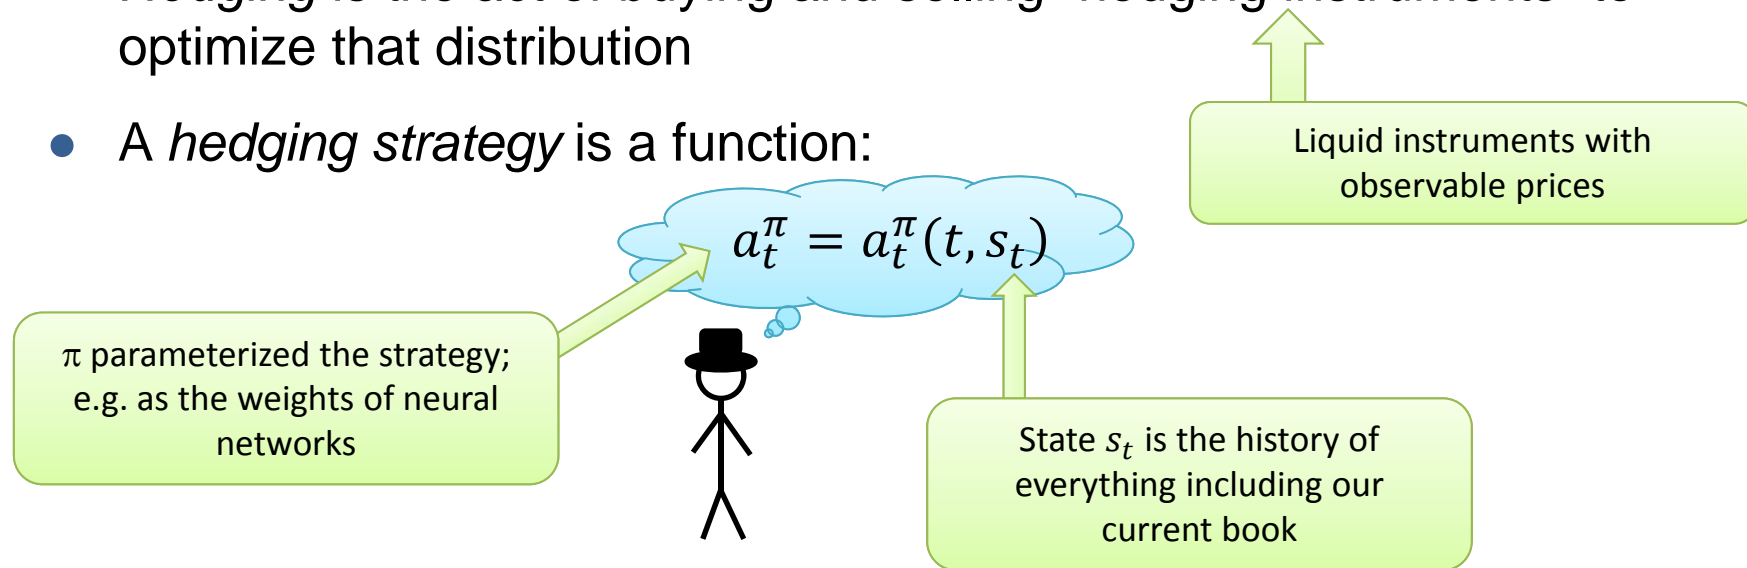

- Example: $X \sim \mathcal{N}(0,1)$
- Plot risk-adjusted value

Bounded by the two extreme risk-adjusted values: risk-neutral and worst-case

Hedging

- We can now express preferences on future profit/loss distributions
- *Hedging* is the act of buying and selling “hedging instruments” to optimize that distribution
- A *hedging strategy* is a function:

- It tells us how much of each hedging instrument to buy or sell at each time t , for every possible state s_t
- Not all actions are possible – in general a_t^π will be subject to limits which are also state-dependent (e.g. short-sell constraints)

Hedging

- How does the hedging strategy π contribute to the terminal profit/loss?

$$w_T(\pi; Z) = \sum_{j=1}^T \delta_j^\pi \cdot h_j + z_j - a_j^\pi \cdot H_j - c_j^\pi$$

δ_j^π : accumulated current positions (“deltas”),
 $\delta_j^\pi = \delta_{j-1}^\pi + a_j^\pi$

h_j : cashflows generated by hedging instruments

Note: all cash flows are discounted

z_j : cashflows from our exotic derivatives portfolio

H_j : mid prices of hedging instruments

c_j^π : transaction costs incurred,
 $c_j^\pi = c(a_j^\pi, s_j)$

Hedging

- The terminal profit/loss is not deterministic – our task is to optimize it
- That means maximizing

$$E[w_T(\pi; z)] = E \left[\sum_{j=1}^T \delta_j^\pi \cdot h_j + z_j - a_j^\pi \cdot H_j - c_j^\pi \right]$$

We apply the value function to the distribution over future real-world states

We need to find the optimal function a_j^π that meets our constraints.

Path dependency

The feasible set of allowed actions a_j^π depends on past decisions $a_{j-1}^\pi \dots a_0^\pi$.

- Two key challenges:
 - How to generate the distribution
 - How to optimize the hedging function

Market simulators

- To generate the profit/loss distribution for a given strategy, we need to simulate future states of the world
 - Prices of available hedging instruments
 - Corresponding cash flows from exotic derivatives
- We should be simulating in the real-world measure, not \mathbb{Q}
 - The real world has “statistical arbitrage”, i.e. with normal risk aversion some trades statistically make money (e.g. shorting options, sell long-dated bonds).
 - Deep Hedging will attempt to take advantage of these opportunities.
 - Absence of arbitrage \Rightarrow absence of statistical arbitrage (e.g. GBM with drift)
 - Existence of arbitrage \Rightarrow existence of statistical arbitrage (e.g. if risk-aversion is very high)
- For the experiments presented here, will use classical \mathbb{Q} models

Optimizing the hedging strategy

- We use a *deep neural network* to represent the strategy a_j^π

- Inputs:

- Current market state
- Relevant product state variables

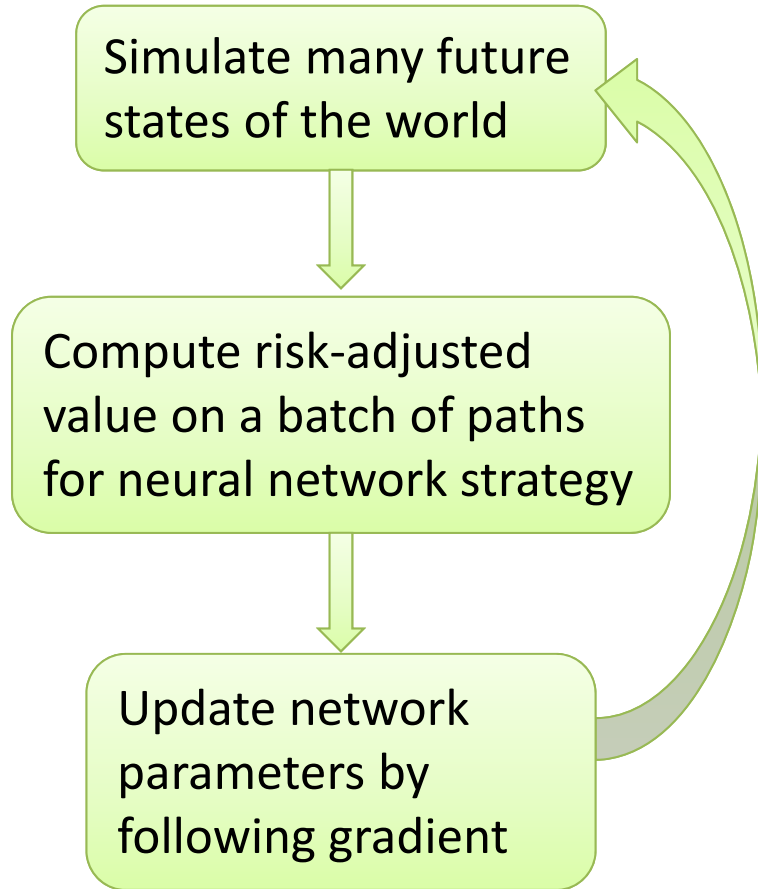

Prices of all hedging instruments

Harvested automatically

- LSTM cells to capture path dependence

- Potentially important when we have transaction costs
- Allows memory of our previous hedging decisions

Deep Hedging

$$\frac{\partial E(w_T(\pi; z))}{\partial W_i}$$

Outline

- Models in an exotic derivatives business
- Teaching a machine to think like a trader
- First steps: toy model trading
- Moving further into the real world

Start simple

- Hedge a short at-the-money 30-day European call

$$z_T = -(S_T - K)^+$$

- Generate paths in Black-Scholes
- Check the impact of transaction costs, risk aversion, and risk limits

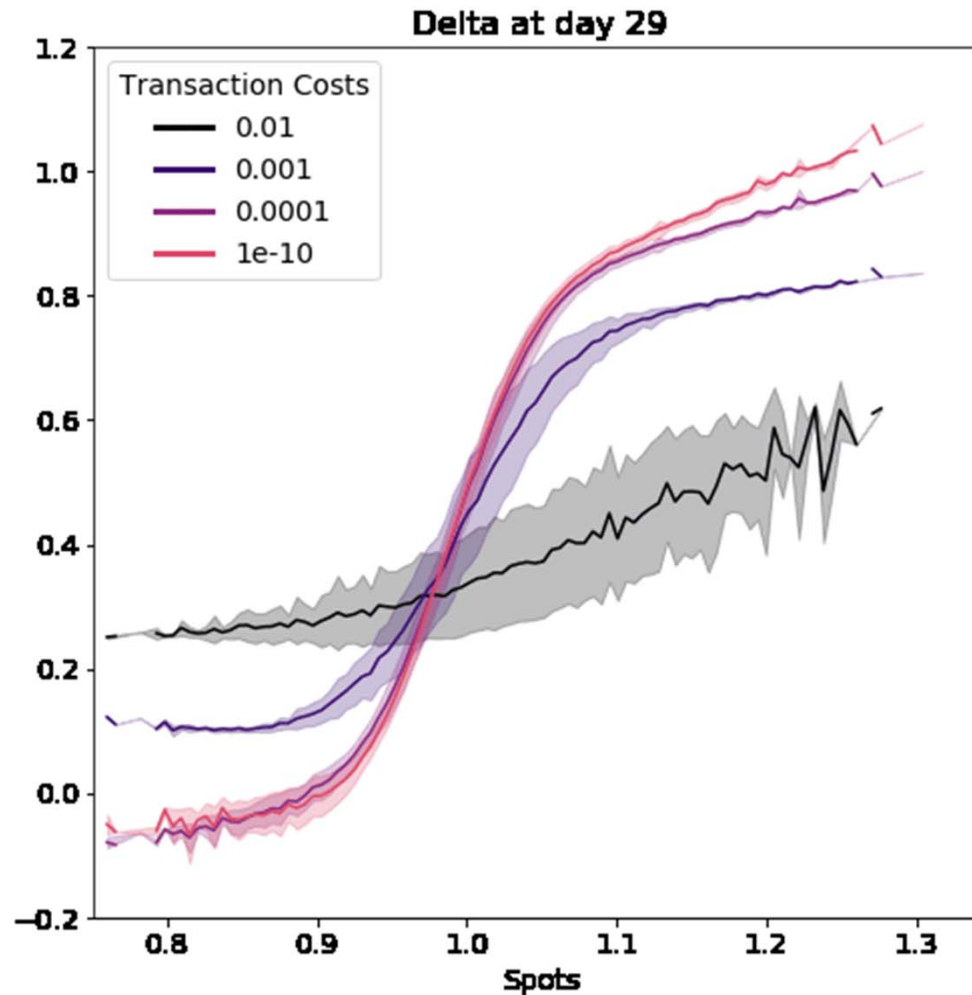

Risk Aversion (Entropy)

- Vanilla option delta
- 10bps cost
- No limits
- Entropic value
- Black-Scholes simulator

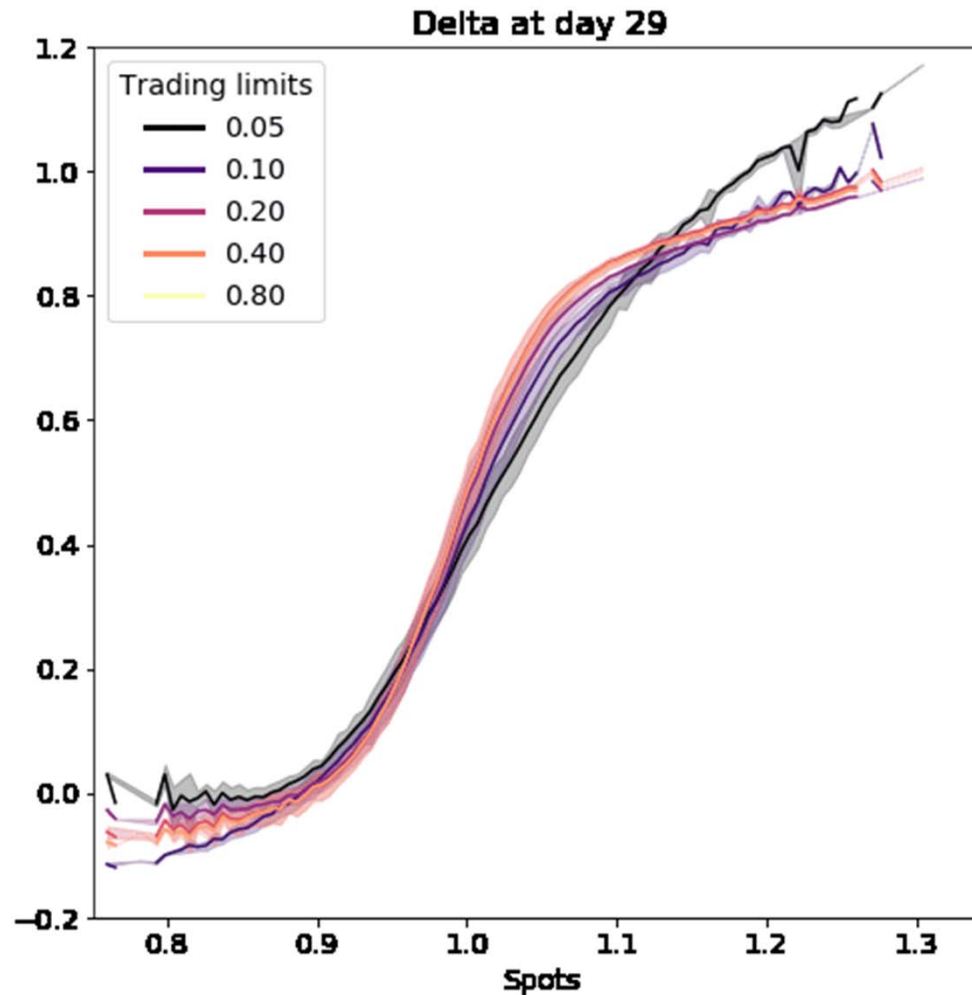

Transaction costs (Entropy)

- Vanilla option delta
- No limits
- Entropic value
- Risk aversion 10
- Black-Scholes simulator

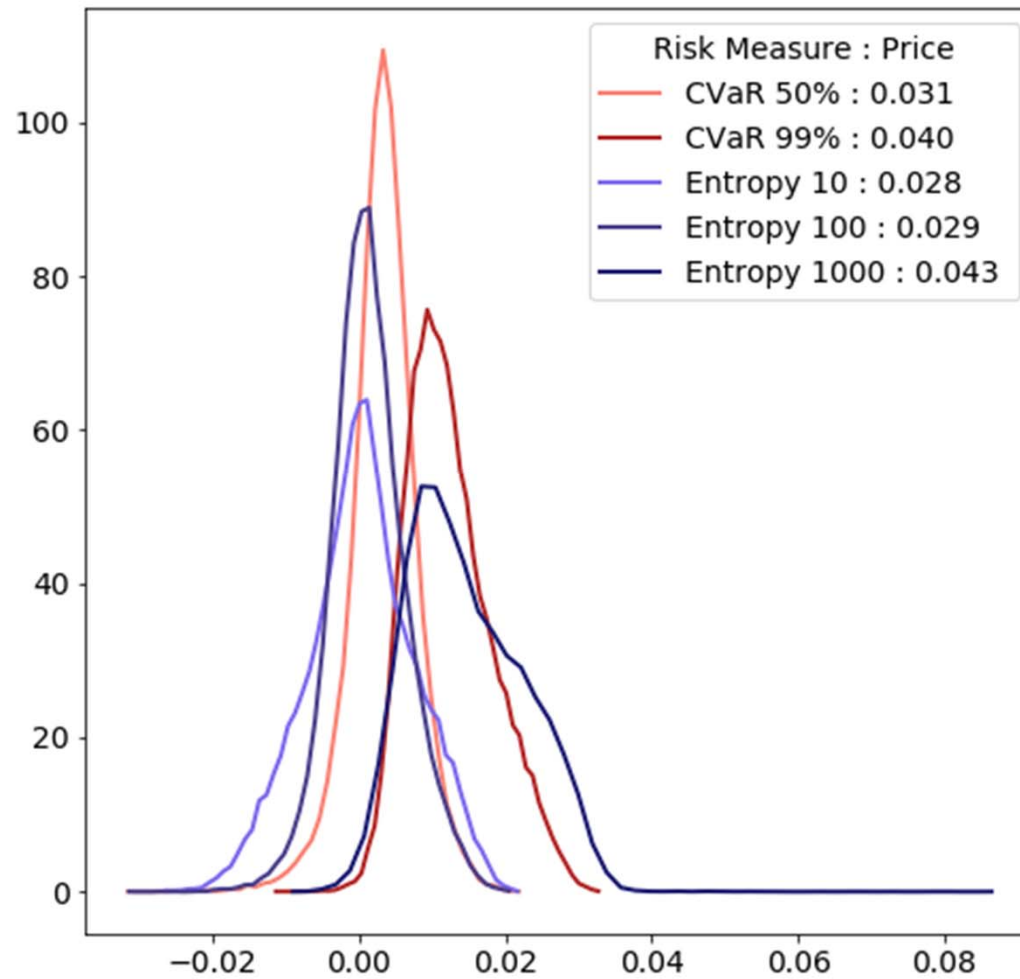

Trading limits

- Vanilla option delta
- 0.01% proportional cost
- Entropic value
- Risk aversion 10
- Black-Scholes simulator

Risk measure

- Vanilla option PnL distribution
- 0.01% cost
- No limits
- Black-Scholes simulator

Forward-starting options

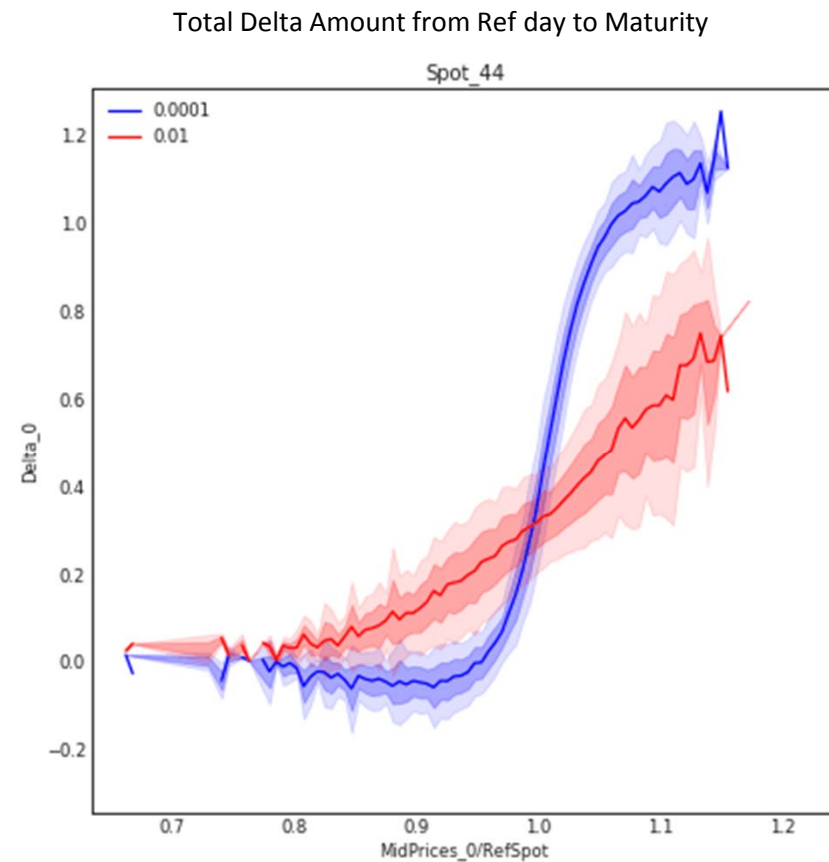

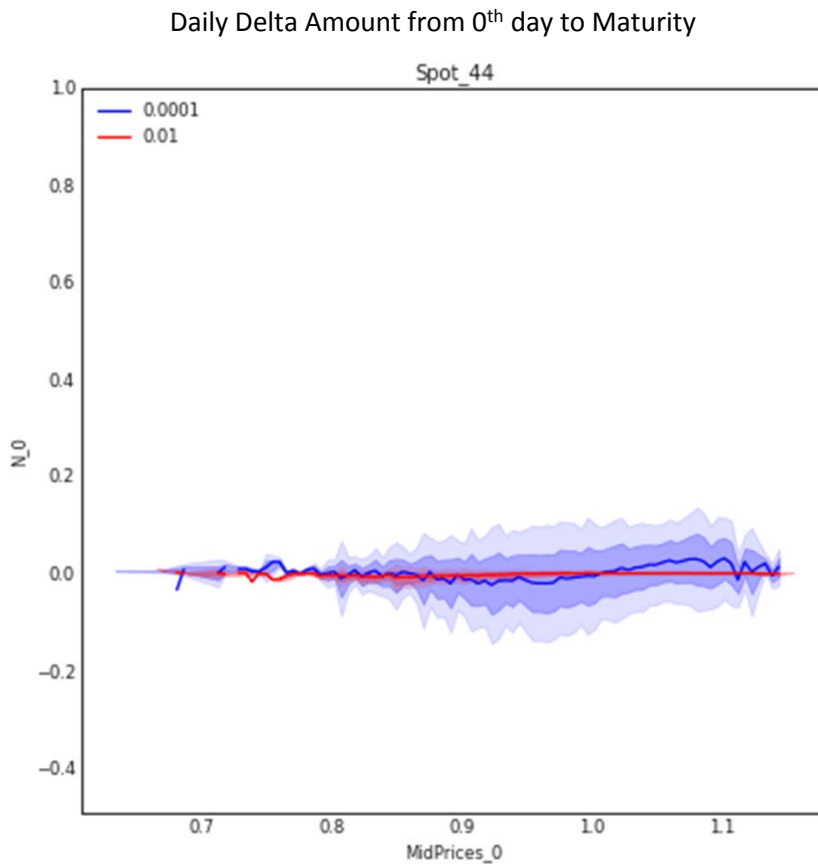

- Increase the complexity: simulate with Heston model
- Compute optimal spot-only hedges for forward-starting options

$$z_T = \max\left(0, \frac{S_T}{S_t} - K\right)$$

- 15-day forward start
- 45-day maturity
- Daily hedging
- Entropic value with risk aversion 50
- No limits

Forward-starting options

- Impact of transaction costs on incremental and total delta

Outline

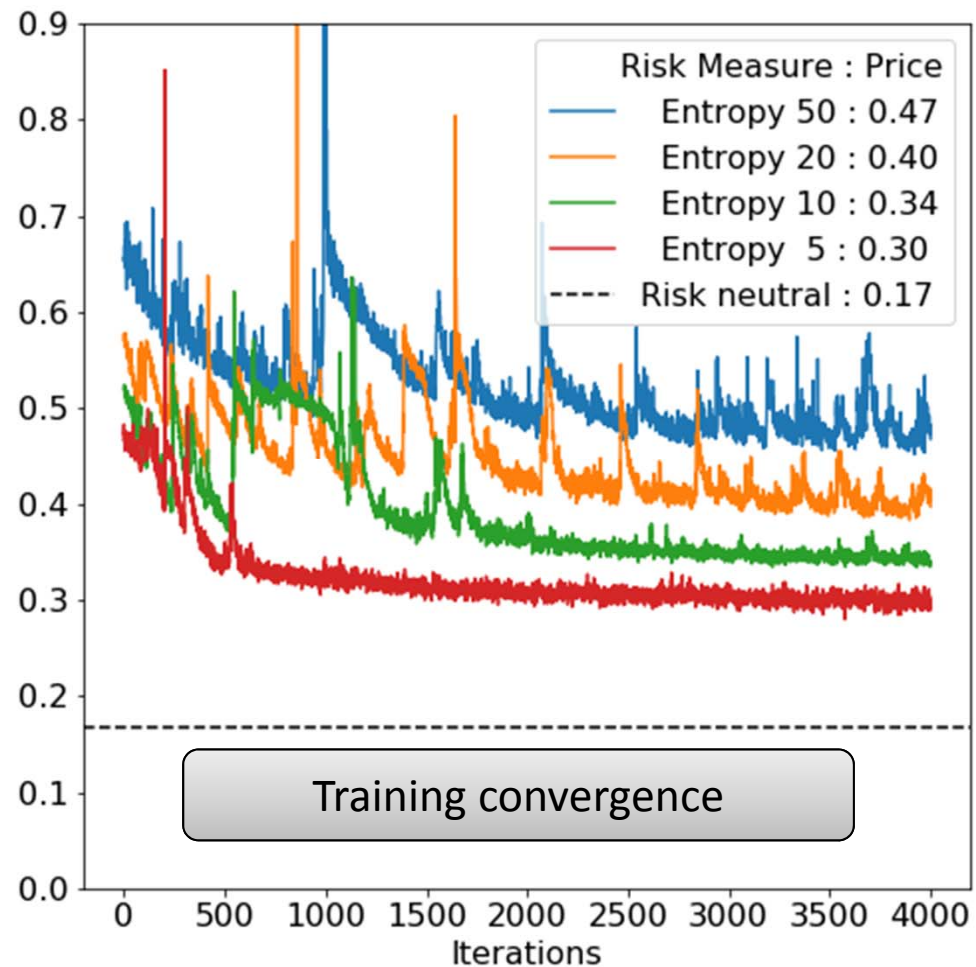

- Models in an exotic derivatives business
- Teaching a machine to think like a trader
- First steps: toy model trading
- Moving further into the real world

“Autocallable” note

- Popular retail payoff:
 - Client is short a down-and-in put paid at maturity
 - Upper knockout barrier
 - Fixed coupons until KO
- 0.1% transaction costs
- No limits
- Risk aversion 20
- Entropic value
- Monthly hedging

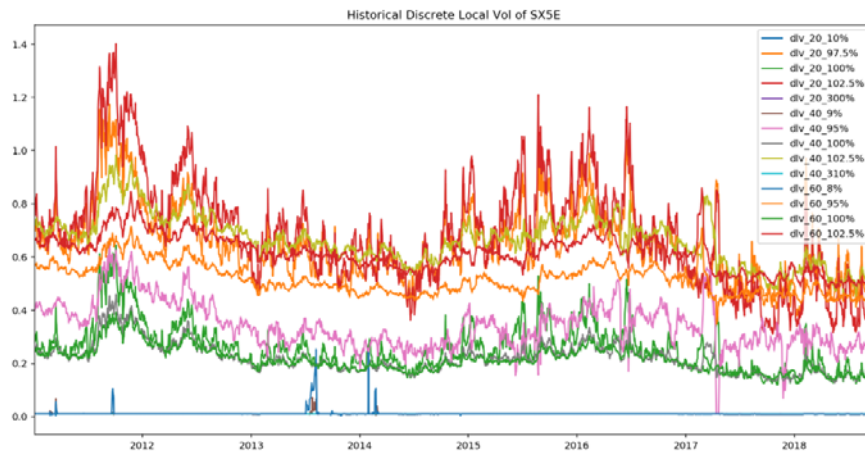

Portfolio of autocallables

- Based on a real portfolio
- 0.1% transaction costs
- No limits
- Local volatility simulator
- Monthly hedging

Market simulator

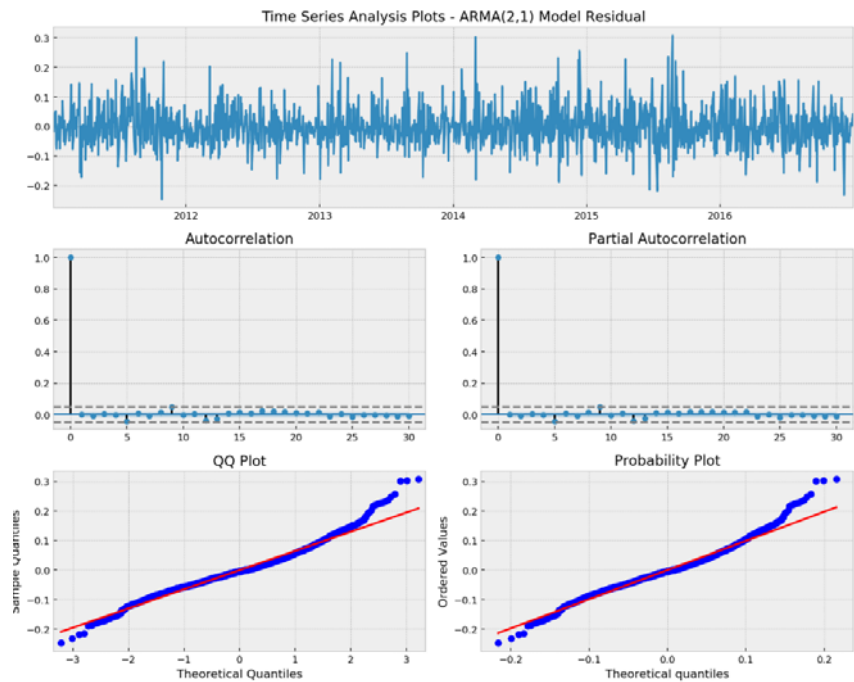

- Go beyond “classical” models – build a statistical model instead

Challenge: avoid arbitrage when simulating options

Simulate discrete local volatilities to avoid static arbitrage

Dynamic arbitrage still a challenge

Market simulator

- How do we build a full statistical market simulator that reflects real-world drifts but is arbitrage-free?
 - Does it need to be fully arbitrage-free?
- What about rare events?
 - A statistical simulator is not likely to capture these well
- In particular, we want the model to behave well in a stress scenario, and to price in the risk appropriately
 - Should we insert stress events into the market simulator?
 - With what probability? Historical likelihood?
- For equities we focused on spot and volatility – there's lots more
 - Rates, spreads, FX, ...

Conclusions

- We formalized the task of pricing and managing the risk of an exotic derivatives portfolio
- Obtaining the optimal hedging strategy is a difficult problem
- Representing the strategy as a neural network makes it tractable
 - Optimization typically takes minutes on CPU for the toy examples here
- So far it works for:
 - Vanillas, cliquets, barrier options, large portfolios
 - With transaction costs and risk limits
 - Simulators based on classical pricing models (Black Scholes, local volatility, Heston)

Many more interesting challenges ahead

- Developing statistical (\mathbb{P}) market simulators for options
- Do we need to compute hedging strategies all the way to maturity?
 - Can we come up with an efficient way to represent a portfolio of exotics as a state?
- How do we choose our risk measure? Can we derive effective real-world risk-measures from the choices people make?
- Go beyond equities: FX, rates, etc.
- Ultimate goal: automated pricing and hedging of exotic derivatives
